

# ECONOMIC RESULTS, CHUKCHI SHELF PROVINCE

(James D. Craig)

## INTRODUCTION

This section summarizes the results of economic modeling using the *PRESTO-5* (Probabilistic Resource *EST*imates-Offshore, version 5) computer program. The economic assessment results are influenced, to a large degree, by the undiscovered, conventionally recoverable oil and gas resources assessed using the *GRASP* (Geologic Resource *AS*essment Program) computer model. The conventionally recoverable results are discussed in separate .pdf files (*Summaries of Play Results, with Cumulative Probability and Ranked Pool Plots* ).

Each province summary page includes three illustrations: (1) cumulative probability plots for risked, conventionally recoverable resource distributions (oil, gas, and BOE); (2) a table comparing risked, mean, conventionally recoverable resources with the risked, mean, economically recoverable resources at current commodity prices; and (3) a price-supply graph displaying economically recoverable resource curves.

The province summary page is followed by a table reporting play-specific, economically recoverable resource estimates for two representative price scenarios: a Base Price scenario (\$18/bbl-oil, \$2.11/MCF-gas) representing current market conditions; and a High Price scenario (\$30/bbl-oil, \$3.52/MCF-gas).

## PROVINCE SUMMARY PAGE

### Risked Cumulative Probability Distributions

The province summary page provides, at page top, cumulative probability distributions for risked, undiscovered endowments of conventionally recoverable oil, gas, and BOE, where resource quantities are plotted against “cumulative frequency greater than %.” A cumulative frequency represents the probability that the resource endowment is equal or greater than the volume associated with that frequency value along one of the curves. For example, a 95% probability represents a 19 in 20 chance that the resource will equal, or be higher than, the volume indicated. Cumulative frequency values typically decrease as resource quantities increase. An expanded description of cumulative probability plots is given in “*Summaries of Play Results, with Cumulative Probabilities and Ranked Pool Plots* ” provided as a

separate .pdf file.

### Table of Risked Play Resources

The province summary page provides, at page center, a table comparing the total conventionally recoverable endowment and the smaller quantity of economically recoverable resources that could be profitably extracted under current economic and engineering conditions. Current prices are represented as \$18 per barrel of oil and \$2.11 per MCF of gas, where gas price is linked to oil price by energy equivalency and discount-value factors (5.62 MCF per barrel; 0.66 value discount). Conventional resource volumes correspond to points on the cumulative probability distributions (at page top). Economic resource volumes correspond to points along the mean price-supply curve (at page bottom). Resources listed as negligible (negl) have volumes lower than the significant figures shown. Not Available (N/A) means that these resources are unlikely to be produced in the foreseeable future because of reservoir conditions or the lack of a viable transportation infrastructure.

The ratio of economic to conventional resources indicates the proportion of the total undiscovered endowment that is profitable to produce under current commodity prices with proven engineering technology. However, for production to occur, commercial discoveries must be made, and the analysis does not imply discovery rates. Given the size and geologic complexity of the offshore provinces, exploration will require extensive drilling, and considering the relatively low chance of commercial success and the high cost of exploration wells, many of these frontier provinces are not likely to be thoroughly tested in the foreseeable future. The ratio of economic to conventional resources should be regarded as an opportunity indicator, rather than as a direct scaling factor for readily available hydrocarbon reserves.

### Price-Supply Curves

The province summary page includes, at page bottom, a graph showing price-supply curves representing Low, Mean, and High resource production scenarios. Price-supply curves illustrate how volumes of economically recoverable resources increase as a function of commodity price. Characteristically, increases in commodity price result

in corresponding increases in economically recoverable resource volumes. The economic resource volumes represent oil and gas, as yet undiscovered, that could be recovered profitably given the modeled economic and engineering parameters. At very high prices, the mean curve approaches the mean total resource endowment estimated by *GRASP*. The price-supply curves do not imply that these resources will be discovered or produced within a specific time frame, only that the opportunity exists for commercial production at levels controlled by commodity prices.

The price-supply curves were generated by the *PRESTO-5* computer program, which simulates the exploration, development, production, and transportation of pooled hydrocarbons in geologic plays within a petroleum province. Economic viability depends on the interaction of many factors defining the size and location of the hydrocarbon pools, the reservoir engineering characteristics, and economic variables relating expenditures to income from future production streams. The economic simulation is quite complex, owing to the complexities in the state of nature, and requires a sophisticated analytical model.

The following is a brief overview of the *PRESTO-5* modeling process. Geologic parameters (for example, reservoir thickness, pool area, risk) used by the *GRASP* computer model to determine conventionally recoverable resources are transferred into the *PRESTO-5* model through an interface program. Economic viability is determined by performing a discounted cash flow analysis on the expenses and modeled production stream for each pool simulated in a given trial. A Monte Carlo (random sampling) process selects engineering parameters (for example, production rate profiles, well spacing, platform installation scheduling), and cost variables (for example, platforms, wells, pipelines) from ranged distributions. Each simulation trial models the expenses, scheduling, and production for pools “discovered” within a particular play. The sampling process is repeated for productive pools in all geologic plays, and the economic resources are aggregated to the province level. The development simulation process is repeated, typically for 1000 trials, at given set of prices (oil and gas prices are linked). After the specified number of trials are completed for the first set of oil and gas prices, a new set of prices is selected and another round of simulation trials is run. This process continues for approximately 30 iterations, yielding a range of economic resource volumes tied to commodity prices. The results for all runs are given as probability distributions, where selected probability levels can be displayed as continuous price-supply curves.

These analyses determine the resource

volumes that are commercially viable under a specific set of current economic and engineering assumptions. No attempt was made to upgrade engineering technology or development strategies that might be implemented in response to higher commodity prices.

The price-supply curves provided in this report are based on the most likely development scenario tailored for each particular province. All provinces were modeled on a stand-alone basis, with engineering assumptions designed for the primary hydrocarbon substance (oil or gas) identified by the *GRASP* analysis. Generally, the secondary hydrocarbon is less economically viable and places an extra burden on the primary hydrocarbon substance. For provinces without existing oil and gas infrastructure, the modeling scenarios were designed assuming that the primary substance would drive initial development in a particular province. Oil-prone provinces were modeled as “oil-only” production, with gas reinjected for reservoir pressure maintenance to maximize oil recovery. Gas-prone provinces were modeled with both gas and oil production because natural gas-liquids (or condensates) are not reinjected. Often the volume of condensates in gas-prone provinces exceeds any volume of non-associated crude oil. All hydrocarbon liquids are commingled in production and transportation systems.

This economic analysis assumes 1995 as the base year. Higher nominal commodity prices in the future (price increases only at the rate of inflation) do not result in higher estimated volumes of economically recoverable resources, whereas higher real commodity prices (increases above the rate of inflation) do increase the economically recoverable resources. The economic model assumes that commodity price and infrastructure costs were inflated equally at an assumed 3% annual inflation rate (flat real price and cost paths). The price-supply curves can be used to project economic resource volumes relative to future price if appropriate discounting back to the 1995 base year is made to account for real price and real costs changes in the intervening years.

The price-supply graph usually contains three curves, corresponding to Low, Mean, and High resource production levels. The Low resource case represents a 95% probability (19 in 20 chance) that the resources are equal to, or exceed, the volumes derived from the price-supply curves. The High resource case represents the 5% exceedance level (1 in 20 chance). The Mean resource case represents the average. In high-cost and high-risk provinces, where there are no economically recoverable resources at the 95% probability level, no “Low” curve is displayed. An apparent anomaly is observed in some cases where the lower tail of the “Mean” price-supply curve indicates

economic resources greater than the “High” (5% probability) curve. This situation occurs at low prices where the probability of economic success drops below 5%, and the Mean curve is obtained from the few productive trials occurring at probabilities below 5%.

A few additional observations concerning price-supply curves are noteworthy. Following established convention for price-supply curves, these graphs are rotated from the usual mathematical display of X-Y plots. Although shown along the vertical (Y) axis, price is the independent variable and resource is the dependent variable. In many of the gas-prone basins, price-supply curves will display an abrupt step below which no risked economically recoverable resources are modeled. This step corresponds to the minimum resource value required to overcome the cost of production and transportation infrastructure. Because of the distances to Asian markets, the assumed destination for Alaska gas production, natural gas must be converted to liquid form for transportation by ships. The infrastructure associated with conversion into liquefied natural gas (or LNG) does not lend itself to incremental additions for grassroots projects; therefore, an abrupt “cost-hurdle” created by large LNG and marine terminal installations must be overcome by significant resource volumes.

Finally, the reader must be aware that these price-supply curves are models of risked hydrocarbon resources. Both the geologic risk that the resources are pooled and recoverable as well as the economic risk that development is profitable under the assumed economic and technologic conditions are factored into the reported results. This means that although very low resource volumes are reported as “economically recoverable”, these low volumes, in fact, do not correspond to actual quantities of oil or gas. At low prices, risk is dominated by economic factors associated with engineering cost and reservoir performance variables. At high prices, risk is dominated by geologic factors related to volumetric variables. **Risked price-supply curves are most appropriately used to define the comparative potential of petroleum provinces under changing price and probability conditions.** They do not predict the timing of resource discovery or rate of conversion of undiscovered resources to future production. As previously stated, future production of the modeled economically recoverable resources will require extensive exploration programs. In the Alaska offshore, future leasing and exploration activities are likely to be driven by “high-side potential”, combining perceptions of greater rewards at higher risk, higher future commodity prices, and innovative technology to reduce costs.

## TABLE FOR PLAY RESOURCE DISTRIBUTIONS

The risked mean contribution for each geologic play in the province is tabulated under two hypothetical price conditions. The Base Price (\$18 per barrel-oil; \$2.11 per MCF-gas) represents current economic conditions. The High Price (\$30 per barrel-oil; \$3.52 per MCF-gas) represents a situation where real price has increased significantly from current levels. Other economic parameters (for example, discount rate and corporate tax rate) were equal in both scenarios, as were engineering technology and cost assumptions. The play number, name, and *UAI* (*Unique Assessment Identifier* code) provide a link to the data presented in other sections of this report. Hydrocarbon substances are distinguished as oil (includes crude oil and gas-condensate liquids), gas (includes non-associated, associated, and dissolved gas), and BOE (gas volume is converted to barrel of oil equivalent and added to oil volume).

## CHUKCHI SHELF MODELING RESULTS

The Chukchi shelf province was modeled for the production of oil, and the scenario relied on existing infrastructure on the North Slope and the Trans-Alaska Pipeline System (TAPS). Chukchi oil production was transported by TAPS and delivered by tankers to U.S. West Coast (Los Angeles) markets.

No Chukchi shelf gas resources are reported as economic. This decision is based on two considerations. First, the huge gas known reserves (25-35 TCFG) on the North Slope remain undeveloped, and no gas transportation infrastructure is present to carry gas to outside markets. Second, if a future liquefied natural gas (LNG) market warrants the large investment (approaching \$15 billion) required for development, the proven onshore gas reserves are likely to fill the new gas transportation system for decades. The economic assessment assumed that solution gas recovered from oil fields will be used as fuel for facilities or reinjected to maximize oil recovery. Non-associated gas pools will not be developed until there is excess capacity in the future gas transportation system. At present, a gas pipeline and LNG plant for North Slope gas production is being considered for the year 2005-2010 time frame.

Under Base Price conditions (\$18 per barrel), 1.14 BBO of risked mean economically recoverable oil is estimated for the Chukchi shelf province, placing it second (below the Beaufort shelf province) among all Alaska offshore assessment provinces. However, only 9% of the huge conventionally recoverable oil resources (13.02 BBO), and none of the conventionally

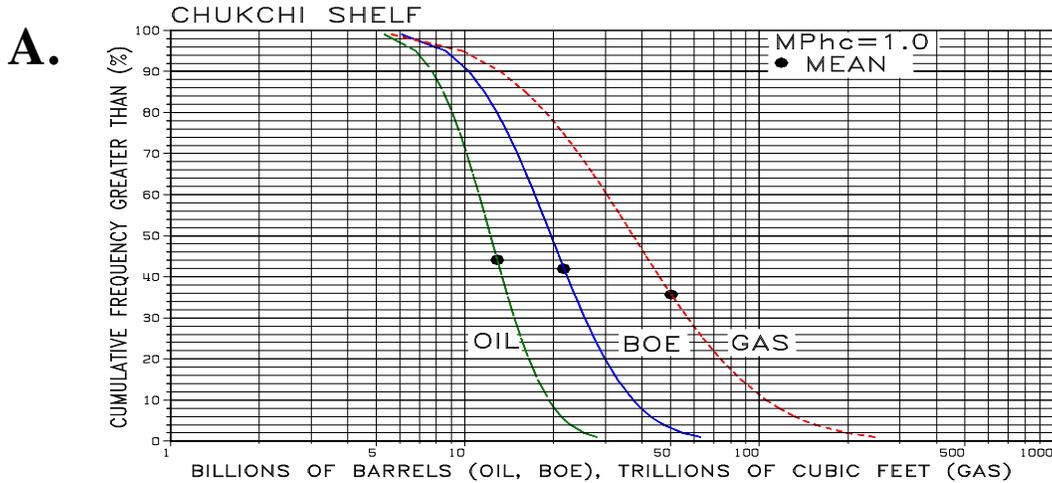

recoverable gas resources (51.84 TCFG), are economically viable at current prices. At High Price conditions (\$30.00 per barrel), the Chukchi shelf province could hold economic resources ranging from 2.8 BBO (Mean resource case) to 6.2 BBO (High resource case).

The economic oil resources are contained in few of the 22 geologic plays identified on the Chukchi shelf. For the Base Price (\$18), 4 plays contain 90% of the economic oil resources. At the High Price (\$30), these same 4 plays contain 86% of the economic oil resources. Two of these plays (Rift-Active Margin, Play 7; U. Brookian-Paleovalleys, Play 21) were tested by exploration wells with favorable, although non-commercial, results. The other two plays (Endicott-Chukchi Platform, Play 1; N. Chukchi High-Sand Apron, Play 14) remain untested by wells and are considered speculative.

The multi-billion barrel, high-side potential and existing infrastructure on the North Slope are two important factors which may attract future exploration efforts to the Chukchi shelf, despite the formidable costs and logistics of operating in this Arctic offshore setting.

**Economic Results for Chukchi shelf assessment province.** (A) Cumulative frequency distributions for **risked, undiscovered conventionally recoverable resources** (B) Table comparing results for conventionally and economically recoverable oil and gas; (C) Price-supply curves for **risked, economic oil** at low (F95), mean, and high (F05) resource cases.

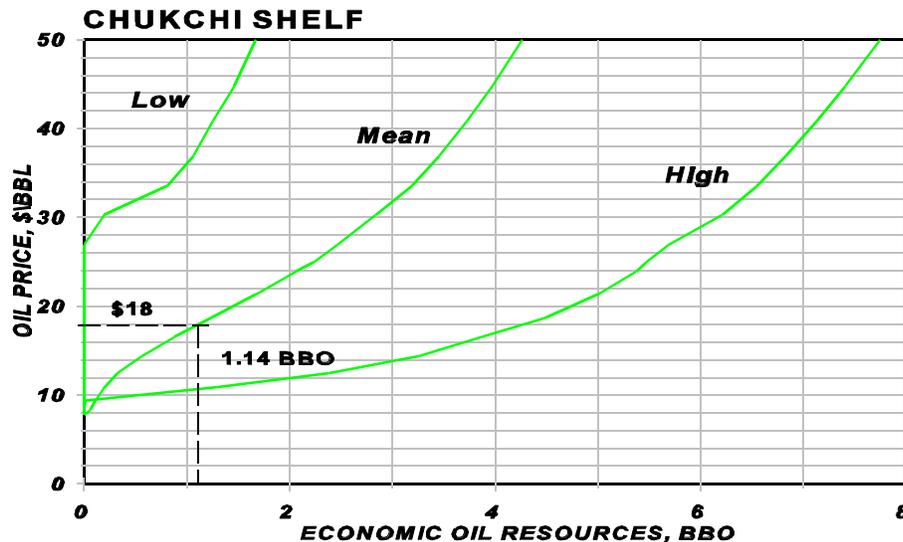

*BOE, total oil and gas in energy-equivalent barrels; MPhc, marginal probability for occurrence of pooled hydrocarbons in basin; BBO, billions of barrels; TCFG, trillions of cubic feet.*

**OIL** is in billions of barrels (BBO). **GAS** is in trillion cubic feet (TCF).

**BOE** is barrel of oil equivalent barrels, where 5,260 cubic feet of gas = 1 equivalent barrel-oil

For direct comparisons among provinces, two prices are selected from a continuum of possible price/resource relationships illustrated on price-supply curves. **BASE PRICE** is defined as \$18.00 per barrel for oil and \$2.11 per thousand cubic feet for gas. **HIGH PRICE** is defined as \$30.00 per barrel for oil and \$3.52 per thousand cubic feet for gas. Both economic scenarios assume a 1995 base year, flat real prices and development costs, 3% inflation, 12% discount rate, 35% Federal corporate tax, and 0.66 gas price discount.

Shaded columns indicate the most likely substances to be developed in this province. Economic viability is indicated on price-supply curves which aggregate the play resources in each province.

N/A refers to "not available". Associated gas will be reinjected for pressure maintenance to maximize oil recovery or as fuel for production facilities. Coproduction of gas resources is not economically feasible because of the lack of a gas transportation system and over 25 TCF of proven and undeveloped gas reserves on the North Slope.
